Abstract

We consider incompressible Stokes flow with an internal interface at which the pressure is discontinuous, as happens for example in problems involving surface tension. We assume that the mesh does not follow the interface, which makes classical interpolation spaces to yield suboptimal convergence rates (typically, the interpolation error in the $L^2(\Omega)$-norm is of order $h^{\frac{1}{2}}$). We propose a modification of the $P_1$-conforming space that accommodates discontinuities at the interface without introducing additional degrees of freedom or modifying the sparsity pattern of the linear system. The unknowns are the pressure values at the vertices of the mesh and the basis functions are computed locally at each element, so that the implementation of the proposed space into existing codes is straightforward. With this modification, numerical tests show that the interpolation order improves to $O(h^{\frac{3}{2}})$.

The new pressure space is implemented for the stable $P_1^+/P_1$ mini-element discretization, and for the stabilized equal-order $P_1/P_1$ discretization. As-
Assessment is carried out for Poiseuille flow with a forcing surface and for a static bubble. In all cases the proposed pressure space leads to improved convergence orders and to more accurate results than the standard $P_1$ space. In addition, two Navier-Stokes simulations with moving interfaces (Rayleigh-Taylor instability and merging bubbles) are reported to show that the proposed space is robust enough to carry out realistic simulations.

**Key words:** Finite elements, interface, interpolation, discontinuous pressure, surface tension

1. Introduction

Though much progress has been made over the last years in the field of finite-element-based computational fluid mechanics, the accurate simulation of flows with significant surface tension effects remains a challenge. This is a consequence of two main difficulties that are inherent to such flows:

(i) The surface tension force $F_\Gamma$ is a surface Dirac distribution over the interface $\Gamma$, proportional to the curvature of $\Gamma$. The singularity of the force, together with its dependence of second derivatives of the interface shape, renders it difficult to approximate.

(ii) Some of the flow variables, most importantly the pressure, are discontinuous across $\Gamma$. This leads to suboptimal interpolation accuracy whenever the finite element interpolants are continuous across $\Gamma$.

In a recent careful study, Gross and Reusken [1, 2] (see also [3]), have shown that both of the aforementioned difficulties need to be specifically
addressed or otherwise the convergence is poor (of order $h^{\frac{1}{2}}$ in the $L^2(\Omega)$-norm). In this article the attention is focused in difficulty (ii), for which Gross and Reusken propose to adopt an XFEM [4] enrichment of the pressure space, incorporating functions that are discontinuous at $\Gamma$, as had been also proposed by Minev et al [5]. With this modification, they are able to get improved convergence behavior, at the expense of the well-known pitfalls of the XFEM methodology: The ill-conditioning of the system matrix due to approximate linear dependence of the basis, and the introduction of new unknowns that depend on the location of the interface, thus requiring the code to completely rebuild the linear system structure for each interface location.

Similar considerations have been made recently by Ganesan et al [6]. They compare mixed finite elements with continuous and discontinuous approximations for the pressure, and end up recommending the use of meshes that follow the interface together with discontinuous pressure interpolants. Clearly, this is the only combination of classical finite elements that yields a pressure space that is discontinuous at $\Gamma$, which is the key to properly tackle difficulty (ii) above. However, in a dynamic simulation it is cumbersome and sometimes impossible to maintain the mesh aligned with the interface, so that other remedies must be sought.

In this article we introduce a novel pressure space which accommodates discontinuities at the (given) interface $\Gamma$, which is approximated by piecewise-linear segments in 2D and piecewise-planar facets in 3D. The proposed space is nothing but the classical conforming $P_1$ space, locally modified at those elements that are cut by the interface (which will be denoted as $interface_{3}$).
elements). The modification is local, computed element-by-element, and it does not introduce any additional degrees of freedom. It is thus extremely easy to incorporate the proposed space into existing codes. Further, the only discontinuities take place at \( \Gamma \), so that no special treatment is needed at other interfaces (such as element-to-element interfaces, for example, as happens with Discontinuous Galerkin methods).

The proposed pressure space will be introduced in the framework of the (two-dimensional for simplicity) problem

\[
\begin{align*}
-\mu \nabla^2 u + \nabla p &= F_\Gamma \quad \text{in } \Omega \\
\nabla \cdot u &= 0 \quad \text{in } \Omega \\
u &= 0 \quad \text{on } \partial \Omega
\end{align*}
\]

where \( F_\Gamma = f \delta_\Gamma \mathbf{n} \), with \( f \) a given function, \( \delta_\Gamma \) the Dirac delta distribution on the line \( \Gamma \), and \( \mathbf{n} \) its normal. The singular force \( F_\Gamma \) acts in fact as a jump condition on the normal stress across \( \Gamma \), namely,

\[
-\mu \partial u_\nu = f,
\]

whereas both the velocity and the tangential stress remain continuous. In fact, in this constant-viscosity case the velocity gradient exhibits no jump across \( \Gamma \) [2], so that (4) reduces to \( p = -f \). Notice that this simplified model also represents the so-called actuator-disk model that is very popular in the analysis of rotors (propellers, wind turbines, etc.) [7, 8, 9, 10, 11].

Denoting by \( V = H^1_0(\Omega) \times H^1_0(\Omega) \) and \( Q = L^2(\Omega)/\mathbb{R} \), the variational formulation that corresponds to (1)-(3) reads: \(^*\)Find \( (u, p) \in V \times Q \) such that

\[
\int_{\Omega} \left( -\mu \nabla^2 u + \nabla p - \mu \nabla \cdot v + q \nabla \cdot u \right) \, d\Omega = \int_{\Gamma} f \cdot \mathbf{n} \, d\Gamma
\]

\(^*\)
for all \((v, q) \in V \times Q\). The bilinear and linear forms associated to the variational formulation will be denoted by \(B(\cdot, \cdot)\) and \(L(\cdot)\), so that (5) can be rewritten as

\[
B((u, p), (v, q)) = L(v, q).
\]

Under reasonable regularity assumptions on \(\Gamma\) and \(f\) this problem admits a unique solution, since it is only necessary that \(L\) be a bounded linear functional. The finite element discretization of (5) is briefly recalled in Section 2, together with the description of the proposed pressure space. Section 3 contains several numerical experiments that assess the advantages of the proposed space with respect to classical spaces. Some conclusions are finally drawn in Section 4.

2. Finite element approximation

2.1. Galerkin mini-element formulation

In the Galerkin formulation, the exact variational formulation is restricted to the space \(V_h \times Q_h\), where \(V_h \subset V\) and \(Q_h \subset Q\) are the approximation spaces for velocity and pressure, respectively. The discrete formulation thus reads “Find \((u_h, p_h) \in V_h \times Q_h\) such that

\[
B((u_h, p_h), (v_h, q_h)) = L(v_h, q_h)
\]

for all \((v_h, q_h) \in V_h \times Q_h\).” As is well-known, for this formulation to be well-posed and convergent it is sufficient that the Babuška-Brezzi stability condition\([12, 13]\) be satisfied:

\[
\inf_{q_h \in Q_h} \sup_{v_h \in V_h} \frac{\int_\Omega q_h \nabla \cdot v_h \ d\Omega}{\|q_h\|_Q \|v_h\|_V} \geq \beta > 0
\]
with $\beta$ a mesh-independent constant.

The pressure and velocity spaces that correspond to the so-called mini-element \[14\] are, for a finite element mesh $\mathcal{T}_h$:

$$
Q_h = Q_h^1 := \{q_h \in Q \cap C^0(\Omega), \ q_h|_K \in P_1(K), \ \forall K \in \mathcal{T}_h\} \quad (9)
$$

$$
V_h = V_{\text{mini}}^h := \{v_h \in V, \ v_h|_K \in (P_1(K) \oplus \text{span}(b_K))^2, \ \forall K \in \mathcal{T}_h\} \quad (10)
$$

where $b_K$ is the cubic bubble function that vanishes on all three edges of $K$.

Notice that the pressure space is nothing but the usual continuous $P_1$ space, while the space for each velocity component has been enriched by the bubble functions so as to satisfy the stability condition. Being stable, this element satisfies the a priori estimate

$$
\|u - u_h\|_V + \|p - p_h\|_Q \leq C \left( \inf_{w_h \in V_h} \|u - w_h\|_V + \inf_{r_h \in Q_h} \|p - r_h\|_Q \right) \quad (11)
$$

where $C$ does not depend on the mesh size $h$. In the case of a smooth solution, there exists a constant $c$ such that $\inf_{w_h \in V_h} \|u - w_h\|_V \leq c h |u|_{H^2(\Omega)}$ whereas $\inf_{r_h \in Q_h} \|p - r_h\|_Q \leq c h^2 |p|_{H^2(\Omega)}$. In the case of non-smooth solutions involving pressure jumps, however, the latter interpolation estimate deteriorates significantly \[2\], to

$$
\inf_{r_h \in Q_h} \|p - r_h\|_Q \leq C \left( h^{\frac{1}{2}} \|[p]\|_{L^\infty(\Gamma)} + h^2 \|p\|_{H^2(\Omega \setminus \Gamma)} \right)
$$

This approximation error of order $h^{\frac{1}{2}}$ is a direct consequence of the pressure interpolants being continuous across $\Gamma$, so that switching to discontinuous-pressure elements does not cure it, unless the mesh follows the interface.

### 2.2. A discontinuous pressure space with the same unknowns

The proposed variant of the mini-element combines the velocity space $V_{\text{mini}}^h$ (Eq. 10) with a new pressure space $Q_h^F$ discussed below, without any
modification of the Galerkin formulation (7).

2.2.1. The finite element interpolant

Let us now propose a different finite element space, denoted by $Q^\Gamma_h$, which has the same unknowns as the conforming $P_1$ space $Q^1_h$ but admits discontinuities across $\Gamma$. For all elements not cut by $\Gamma$ standard $P_1$ interpolants are chosen. The only modifications appear in interface elements.

Consider the triangle $ABC$, which is cut by $\Gamma$ into subtriangle $APQ$ and subquadrilateral $BCQP$ (see Fig. 1). We assume for simplicity that, locally, $\Gamma$ is approximated by linear segments (this would probably add an additional error of order $h^2$, much smaller than the other errors involved). Let $p_A, p_B, p_C$ denote the nodal values of the discrete pressure $p_h$, to be interpolated in the triangle $ABC$.

Let us arbitrarily denote the triangle $APQ$ the “green” side of $\Gamma$ and quadrilateral $BCQP$ the “red” side. For the approximation to be discontinuous, the function $p_h$ on the green side needs to be solely determined by the only green node, i.e., $A$. Similarly, $p_h$ on the red side must depend on just $p_B$ and $p_C$. To accomplish this, we simply “carry” the value at each node towards the intersection of any edge emanating from it with the interface.

In this way, on the green side of $\Gamma$, the values at $P$ and $Q$ will be $p_A$, and thus $p_h$ will be constant:

$$p_h|_{APQ} = p_A$$

On the red side, the value at $P$ will be $p_B$ and the value at $Q$ will be $p_C$. One can here choose either to adopt a $Q_1$ interpolation in $BCQP$ from these nodal values, or subdivide the quadrilateral into two triangles, $BCP$ and $CQP$. In any case, since the nodal values are given, the interpolation is immediate.
For the red triangle $CQP$, for example, $p_h$ will be the linear function that takes the value $p_C$ at vertex $C$, the value $p_Q$ at vertex $Q$, and the value $p_P$ at vertex $P$. Notice that this interpolation leads to $p_h$ being discontinuous only at $\Gamma$, since the function $p_h$ restricted to any edge of the triangle is uniquely determined by the values at the nodes lying at the endpoints of that edge.

As a consequence of carrying the nodal values towards the intersection of each edge with the interface, the space $Q_h^\Gamma$ consists of functions with locally an oblique derivative (in the direction of the edge that happens to cross $\Gamma$ at each point) equal to zero. The interpolation error $\|p-I_h p\|_Q$ is thus expected to be of order $h^{3/2}$ for arbitrary $p \in W^{1,\infty}(\Omega \setminus \Gamma)$.

Remark: It could be interesting to modify the proposed space in such a way as to obtain an interpolation order of $h^2$ for functions with any derivative at $\Gamma$. A suitable way to do this would be by extrapolation along the edge using some recovered gradient at the nodes. This is an operation that cannot be carried out at the element level alone, and has not been explored in this work.

Remark: Some modifications are needed if the interface $\Gamma$ ends within the domain (i.e., a cracked domain). Consider that the interface ends at some point $T$ that lies between $P$ and $Q$, so that the segment $TQ$ is not contained in $\Gamma$. In this case the value of $p_h$ at $Q$ is computed by linearly interpolating the values $p_A$ and $p_C$ along the edge $AC$. The treatment of the intersection point $P$ is as before, so that the interpolant is continuous at $Q$ and discontinuous at $P$.

The extension of the proposed methodology to three dimensions follows the lines described above. For completeness, the basis functions are given
explicitly for the different possible cases in the paragraphs that follow.

2.2.2. Two-dimensional case: Standard interface element

Consider as before the triangle $ABC$, which is cut by $\Gamma$ into the “green” subtriangle $APQ$ and the “red” subtriangles $BCP$ and $CQP$. The basis functions $N_A$, $N_B$ and $N_C$ are defined to be piecewise affine inside each of these subtriangles. It only remains to define their values at the vertices of the subtriangles, i.e., at the points $A$, $B$, $C$, $P$ and $Q$. However, since they are discontinuous at $\Gamma$, two values are given at points $P$ and $Q$. The values on the green side will be assigned a “plus” sign, while those on the red side a “minus” sign. The values at the vertices are:

\[
\begin{align*}
N_A(A) &= 1 & N_B(A) &= 0 & N_C(A) &= 0 \\
N_A(B) &= 0 & N_B(B) &= 1 & N_C(B) &= 0 \\
N_A(C) &= 0 & N_B(C) &= 0 & N_C(C) &= 1 \\
N_A(P^+) &= 1 & N_B(P^+) &= 0 & N_C(P^+) &= 0 \\
N_A(P^-) &= 0 & N_B(P^-) &= 1 & N_C(P^-) &= 0 \\
N_A(Q^+) &= 1 & N_B(Q^+) &= 0 & N_C(Q^+) &= 0 \\
N_A(Q^-) &= 0 & N_B(Q^-) &= 0 & N_C(Q^-) &= 1
\end{align*}
\]

Notice that these functions satisfy several useful properties: (i) They form a nodal basis, in the sense that they take the value one at their corresponding node and zero at the other nodes; (ii) their sum equals the constant function equal to one in $K$; (iii) their extreme values (zero and one) take place at the nodes. A picture of the interpolation functions for this case can be seen on Fig. 2.
Remark: Though unlikely in practical cases, it could happen that $\Gamma$ passes exactly through a vertex. This is a degenerate case in which one of the subtriangles becomes a needle of vanishingly small volume.

2.2.3. Two-dimensional case: Element containing an interface endpoint

In the case that $\Gamma$ has an endpoint at element $K$, special basis functions are needed. Consider $P$ to be the last edge-interface intersection point, and $T$ to be the interface endpoint (see Figure 3). The point $Q$ is defined as the intersection of the line $PT$ with the edge $AC$. The difference with the previous case is that now the functions need to be continuous at point $Q$.

For this purpose, let $g$ be an affine function defined on the edge $AC$ such that $g(A) = 1$ and $g(C) = 0$ (in other words, $g$ is the restriction to edge $AC$ of the $P_1$ basis function corresponding to node $A$). The values of $N_A$, $N_B$ and $N_C$ at points $A$, $B$, $C$, $P^+$ and $P^-$ are as in (12)-(16). At point $Q$ the functions are continuous, with values

$$N_A(Q) = g(Q), \quad N_B(Q) = 0, \quad N_C(Q) = 1 - g(Q) \quad (19)$$

Properties (i)-(iii) above are also satisfied by this basis. An illustration of these functions can be seen on Fig. 4.

2.2.4. Three-dimensional case: Standard interface element

Consider that the element $K$ cut by the interface is the tetrahedron $ABCD$ as shown in Fig. 5, of which either three (case (a)) or four (case (b)) edges are cut by $\Gamma$.

In case (a), there appear three intersection points $P$, $Q$ and $R$ (see Fig. 5(a)), at which the nodal functions $N_A$, $N_B$, $N_C$ and $N_D$ are bi-valued. As
in the two-dimensional case, the plus and minus values at the intersection points correspond to the “green” and “red” sides of the interface. Carrying the values to the interface as explained, the values of the basis functions at the vertices and intersection points are:

\[ N_A(A) = 1, \quad N_B(A) = 0, \quad N_C(A) = 0, \quad N_D(A) = 0 \] (20)
\[ N_A(B) = 0, \quad N_B(B) = 1, \quad N_C(B) = 0, \quad N_D(B) = 0 \] (21)
\[ N_A(C) = 0, \quad N_B(C) = 0, \quad N_C(C) = 1, \quad N_D(C) = 0 \] (22)
\[ N_A(D) = 0, \quad N_B(D) = 0, \quad N_C(D) = 0, \quad N_D(D) = 1 \] (23)
\[ N_A(P^+) = 1, \quad N_B(P^+) = 0, \quad N_C(P^+) = 0, \quad N_D(P^+) = 0 \] (24)
\[ N_A(P^-) = 0, \quad N_B(P^-) = 1, \quad N_C(P^-) = 0, \quad N_D(P^-) = 0 \] (25)
\[ N_A(Q^+) = 1, \quad N_B(Q^+) = 0, \quad N_C(Q^+) = 0, \quad N_D(Q^+) = 0 \] (26)
\[ N_A(Q^-) = 0, \quad N_B(Q^-) = 0, \quad N_C(Q^-) = 1, \quad N_D(Q^-) = 0 \] (27)
\[ N_A(R^+) = 1, \quad N_B(R^+) = 0, \quad N_C(R^+) = 0, \quad N_D(R^+) = 0 \] (28)
\[ N_A(R^-) = 0, \quad N_B(R^-) = 0, \quad N_C(R^-) = 0, \quad N_D(R^-) = 1 \] (29)

The truncated tetrahedron \( BCDPQR \) is divided into subtetrahedra and from the values at the vertices given above the basis functions are obtained by affine interpolation over each subtetrahedron. Satisfaction of 3D analogs of properties (i)-(iii) is straightforward. In this case, for the resulting interpolant not to be discontinuous at the faces (outside \( \Gamma \)) the neighbor element must be subdivided in a compatible way. For face \( ABC \), for example, continuity of \( N_B \) and \( N_C \) is only obtained if both elements sharing this face divide the quadrilateral \( BCPQ \) by the same diagonal.

In case (b) there appear four intersection points, namely \( P, Q, R \) and
S (see Fig. 5(b)). The values of the basis functions at A, B, C and D are obviously the same as in (20)-(23). The values at the intersection points follow the same procedure as before, yielding

\[ N_A(P^+)=1, \quad N_B(P^+)=0, \quad N_C(P^+)=0, \quad N_D(P^+)=0 \]  
\[ N_A(P^-)=0, \quad N_B(P^-)=0, \quad N_C(P^-)=1, \quad N_D(P^-)=0 \]  
\[ N_A(Q^+)=1, \quad N_B(Q^+)=0, \quad N_C(Q^+)=0, \quad N_D(Q^+)=0 \]  
\[ N_A(Q^-)=0, \quad N_B(Q^-)=0, \quad N_C(Q^-)=0, \quad N_D(Q^-)=1 \]  
\[ N_A(R^+)=0, \quad N_B(R^+)=1, \quad N_C(R^+)=0, \quad N_D(R^+)=0 \]  
\[ N_A(R^-)=0, \quad N_B(R^-)=0, \quad N_C(R^-)=1, \quad N_D(R^-)=0 \]  
\[ N_A(S^+)=0, \quad N_B(S^+)=1, \quad N_C(S^+)=0, \quad N_D(S^+)=0 \]  
\[ N_A(S^-)=0, \quad N_B(S^-)=0, \quad N_C(S^-)=0, \quad N_D(S^-)=1 \]  

Properties (i)-(iii) are easily seen to hold, while continuity across the faces again depends on the compatibility of the subdivisions between neighboring elements.

2.2.5. Three-dimensional case: Interface with boundary

If the interface \( \Gamma \) has a boundary \( \partial \Gamma \) within the domain, the basis functions need to be modified in much the same way as in the two-dimensional case. Let \( K \) be an element cut by the surface \( \Gamma \) and such that \( \partial \Gamma \cap K \neq \emptyset \). We assume that \( \Gamma \cap K \) is a planar polygon and thus the intersection of this plane with the edges of \( K \) defines the points \( P, Q, R \) and, in a case-(b) situation, \( S \), as before.

Consider for example that the intersection is as shown in Fig. 6, so that the subdivision corresponds to case (b). Notice, however, that the edge
$BD$ is not crossed by the interface, so that the basis functions must be continuous along this edge and thus, in particular, at point $S$. Proceeding as in the two-dimensional case, we assign to $S$ a unique value provided by the linear interpolation between nodes $B$ and $D$. This procedure is adopted for all intersection points falling outside $\Gamma$. Properties (i)-(iii) are easily seen to hold, as well as continuity of the basis functions across the faces (again depending on a compatible choice of diagonals for quadrilaterals).

2.3. A stabilized method

It is also possible to consider finite element formulations that do not satisfy the Babuška-Brezzi condition (8), but are rendered convergent by means of stabilization techniques [15, 16]. This is the case of the equal-order $P_1/P_1$ formulation in which the discrete spaces are

\begin{align}
Q_h &= Q_h^1 \quad \text{(as before)} \\
V_h &= \{v_h \in V, v_h|_K \in P_1(K)^2, \forall K \in T_h\} \tag{39}
\end{align}

and the formulation reads: “Find $(u_h, p_h) \in V_h \times Q_h$ such that

\[ B((u_h, p_h), (v_h, q_h)) + \sum_{K \in T_h} \tau_K \int_K R(u_h, p_h) \cdot \nabla q_h \, dK = L(v_h, q_h) \tag{40} \]

for all $(v_h, q_h) \in V_h \times Q_h$”. The stabilization coefficient $\tau_K$ is taken as

\[ \tau_K = \frac{h_K^2}{4\mu} \]

where $h_K$ is the element size, and the residual is defined as

\[ R(u_h, p_h) = -\mu \nabla^2 u_h + \nabla p_h - F_\Gamma. \tag{41} \]
For regular forces (e.g., forces in $L^2(\Omega)$, which is not the case of $F_\Gamma$), it is possible to prove an error estimate [16] which is essentially equivalent to (11).

To our knowledge, no analysis exists of stabilized methods in problems involving singular forces. Our approach is to set $\tau_K$ to zero whenever the element $K$ is cut by the interface. Though this could potentially lead to lack of stability, no spurious pressure modes were detected in any of the numerical tests. We attribute this to the band-like structure of the submesh in which the stabilization is omitted, which is too narrow (just one band of elements) for spurious modes to develop. In a different context, Lew and Buscaglia [17] observed that switching the elements crossed by $\Gamma$ to a discontinuous Galerkin discretization required no stabilization, though the same space indeed requires stabilization when used in the whole domain.

3. Numerical experiments

In this section we carry out numerical assessments of the proposed space. We first investigate the interpolation accuracy of the space $Q_\Gamma^h$ and indeed obtain the claimed $h^{3/2}$-order in the $L^2(\Omega)$-norm. Then we turn to academic Navier-Stokes tests with analytic solution in which $Q_\Gamma^h$ is used as pressure space. These tests show that the new space does not deteriorate the stability properties of either the stable mini-element formulation or the stabilized equal-order formulation. Finally, two more realistic problems are simulated to show that the proposed method is robust enough to handle arbitrarily moving interfaces in two and three dimensions.
3.1. Interpolation properties of the space $Q_h^\Gamma$

We first assess purely the interpolation properties of $Q_h^\Gamma$. For this purpose we perform tests similar to those conducted by Reusken [3]. Let $\Omega = (-\pi/2, \pi/2) \times (-\pi/2, \pi/2)$ and let $\Gamma = \{(x, y) \in \Omega | x = 0, y > 0\}$. Let $p$ be the function

\[
p(x, y) = \begin{cases}
  e^{-x} \sin^2(y) & \text{if } (x > 0 \text{ and } y > 0) \\
  0 & \text{otherwise}
\end{cases}.
\]

(42)

Notice that $\Gamma$ is a “crack” in the domain, and that $p$ is discontinuous across $\Gamma$.

The interpolant $I_h p$ of $p$ is now defined as the unique element of $Q_h^\Gamma$ that coincides with $p$ at all the vertices of $I_h$.

A sequence of unstructured meshes was built, of which the first one is shown in Fig. 7. To this mesh, which consists of 326 triangles, we assign a mesh size of $h = 0.2$. The following meshes in the sequence are built by successively dividing each of the triangles of the previous mesh into four equal triangles, leading to meshes with $h = 0.1$, $h = 0.05$ and so forth, until the finest mesh with $h = 3.125 \times 10^{-3}$.

We measured the error of $p - I_h p$ in the $L^2(\Omega)$-norm. The results are shown in Table 1, in which we also include the interpolation error of the $P_1$-conforming interpolant for comparison ($Q_h^1$). Figure 8 displays the convergence rate of the order of $h^{3/2}$.

3.2. Couette flow

In this experiment we consider the domain $[0, L] \times [0, H]$, with periodic boundary conditions in the $x_1$-direction. The velocity is set to zero at the
top and bottom boundaries

\[ u(x_1, x_2 = 0) = u(x_1, x_2 = H) = 0 \]

and the interface \( \Gamma \) is a straight vertical line \( x_1 = a \), on which a constant unit normal force \( f = 1 \) is imposed. The exact solution for this problem is

\[
\begin{align*}
    u_1(x_1, x_2) &= \frac{1}{2\mu L} x_2 (H - x_2) \quad (43) \\
    u_2(x_1, x_2) &= 0 \quad (44) \\
    p(x_1, x_2) &= -\frac{1}{L} x_1 + \mathcal{H}(x_1 - a) \quad (45)
\end{align*}
\]

where \( \mathcal{H}(x_1 - a) = 1 \) if \( x_1 > a \) and zero otherwise, and the indeterminacy of the pressure was removed by imposing \( p(0, 0) = 0 \) instead of setting the average to zero, for simplicity.

This problem, with \( L = 3, H = 1, \mu = 1 \) and \( a = 2 \) was discretized both with the mini-element and with the stabilized equal-order methods. In both cases, the classical \( P_1 \)-conforming pressure space (denoted by \( Q_1^h \) above) and the new space \( Q_{\Gamma}^h \) were implemented.

As in the previous section, a sequence of unstructured meshes was built, of which the first one is shown in Fig. 9. To this mesh, which consists of 220 triangles, we assign a mesh size of \( h = 0.176 \). The following meshes in the sequence are built by subdivision. We measure the velocity error in the \( H^1(\Omega) \)-norm and the pressure error in the \( L^2(\Omega) \)-norm for both methods as functions of \( h \). The results of the convergence analysis are displayed in Table 2 and Fig. 10. The experimental orders of convergence are

\[
\|u - u_h\|_{H^1(\Omega)} = \mathcal{O}(h^{\frac{1}{2}}), \quad \|p - p_h\|_{L^2(\Omega)} = \mathcal{O}(h^{\frac{3}{2}})
\]
for the standard $Q_h^1$ space; and
\[
\|u - u_h\|_{H^1(\Omega)} = \mathcal{O}(h), \quad \|p - p_h\|_{L^2(\Omega)} = \mathcal{O}(h)
\]
for the proposed method. The optimal convergence of smooth problems is thus recovered with the proposed modification of the pressure space.

The pressure field corresponding to the classical mini-element is compared to that obtained with the proposed method in Fig. 11. As is clear from the figure, the improved pressure space exhibits significantly smaller pressure oscillations near the interface than the mini-element.

### 3.3. Static two-dimensional bubble

The second example we report here concerns a 2D static bubble. In this case the interface $\Gamma$ is the circle of radius $R$ centered at the origin. On $\Gamma$, a constant (inwards) normal force is imposed, $f = \frac{\sigma}{R}$, where $\sigma$ represents the surface tension. Setting the pressure outside the bubble arbitrarily to zero, the exact pressure inside the bubble equals $\frac{\sigma}{R}$. The exact velocity vanishes everywhere.

In this example we approximate $\Gamma$ by $\Gamma_h$, which consists of straight segments inside each element that join the intersections of $\Gamma$ with the element edges (i.e., the points $P$ and $Q$ are joined by a straight segment). With $\Gamma_h$ fixed, we impose the surface tension force in two ways:

**Direct forcing:** We impose
\[
F_\Gamma = -\frac{\sigma}{R} \delta_{\Gamma_h} \mathbf{e}_r
\]
where $\mathbf{e}_r$ is the radial unit vector, leading to
\[
L(v_h, q_h) = -\frac{\sigma}{R} \int_{\Gamma_h} \mathbf{e}_r \cdot v_h \, d\Gamma
\]
**Laplace-Beltrami forcing:** The Laplace-Beltrami treatment of surface tension is based on the identity (valid for a closed surface of curvature $\kappa$)

$$\int_{\Gamma} \kappa \, n \cdot v \, d\Gamma = - \int_{\Gamma} (I - n \otimes n) : \nabla v \, d\Gamma$$  \hspace{1cm} (48)

where $I$ is the identity tensor, the symbol $\otimes$ denotes the tensor product, and “:” stands for the double contraction of rank two tensors. This leads to the following linear form on the right-hand side of (7) and/or (40):

$$L(v_h, q_h) = -\sigma \int_{\Gamma_h} (I - n_h \otimes n_h) : \nabla v_h \, d\Gamma$$  \hspace{1cm} (49)

where $n_h$ is the unit normal to $\Gamma_h$.

For the numerical tests we chose $R = \mu = \sigma = 1$, and the domain was set to $\Omega = (-2, 2) \times (-2, 2)$. The velocity is set to zero on $\partial \Omega$, and the pressure at the left bottom corner of the domain is set to zero to fully determine the pressure. We present results for the mini-element formulation with direct forcing (ME+DF), and for the stabilized formulation with Laplace-Beltrami forcing (ST+LB). A mesh refinement study was conducted in the same way as in the previous examples, starting with the mesh shown in Fig. 12, to which we assign $h = 0.2$. Logarithmic plots of the velocity and pressure errors are shown in Fig. 13. Clearly, both methods converge with order $O(h^{1.5})$ if the standard pressure space $Q^1_h$ is used, while switching to $Q^\Gamma_h$ improves the order to $O(h^{2.5})$. The obtained pressure and velocity fields on the mesh with $h = 0.05$, which consists of 14900 elements, are shown in Figs. 14 and 15 for the ME+DF formulation, and in Figs. 16 and 17 for the ST+LB formulation. The improvements brought by the proposed method are evident. The parasitic velocities obtained with the ME+DF formulation have
a maximum modulus of $1.6 \times 10^{-3}$ when the $P_1$ space is used for pressure, whereas with the proposed space this value is much smaller ($4.5 \times 10^{-5}$). Similarly, in the ST+LB formulation the maximum velocity modulus is $2.4 \times 10^{-3}$ for $Q^1_h$ and $7 \times 10^{-5}$ for $Q^p_h$.

3.4. Rayleigh-Taylor instability

This is a well-known benchmark which has been computed by Puckett et al [18], Popinet and Zaleski [19] and Jahanbakhsh et al [20], among others. It consists of a layer of heavier fluid ($\rho = 1.225$) on top of a lighter fluid ($\rho = 0.1694$), both with viscosity $\mu = 3.13 \times 10^{-2}$. The domain is the rectangle $\Omega = (0, 1) \times (0, 4)$ and the gravity is taken as $g = 10$. The interface between the fluids is a horizontal line with a sinusoidal perturbation of amplitude 0.05. We consider the standard case, with no surface tension, and also simulate a case with $\sigma = 0.025$ in which the ability of the numerical method to reproduce the stabilizing effect of surface tension is tested.

To carry out this simulation (and the one in the next subsection) the proposed pressure space was incorporated into a general purpose in-house interface-capturing code that simulates fluids with evolving interfaces. The details of the code are explained elsewhere [21]. Let us here simply summarize its basic ingredients:

- Stabilized equal-order formulation of the time-dependent Navier-Stokes equations.

- Level set formulation for interface representation and transport. Standard $P_1$ conforming elements for the level set function $\phi$. The transport
of \( \phi \) is handled with the SUPG method [22], with mass-preserving periodic reinitialization as proposed by Mut et al [23].

- Laplace-Beltrami treatment of the surface tension force.

Numerical results at several times, as computed on a uniform mesh consisting of 331,776 elements with a time step \( \Delta t = 6.25 \times 10^{-4} \) are shown in Fig. 18. The results with \( \sigma = 0 \) are in good agreement with those reported by Jahanbakhsh et al [20], while the stabilizing effect of surface tension is clear from the simulation results with \( \sigma = 0.025 \).

3.5. Merging bubbles

This experiment shows the good behavior of the proposed method in three-dimensional complex cases. We study the rise of two buoyant bubbles \((\rho = 0.04, \mu = 5 \times 10^{-3})\) in a quiescent liquid with \( \rho = 1 \) and \( \mu = 0.1 \). The diameter of the bubbles is 1 and the domain is \( \Omega = (0, 3) \times (0, 3) \times (0, 4) \). The gravity is \( g = 10 \), the surface tension \( \sigma = 0.2 \) and the initial positions of the bubbles’ centers are \((1.5, 1.5, 2.25)\) and \((1.5, 1.75, 1)\) (notice that they are not vertically aligned).

The finite element mesh consists of 885,000 tetrahedra, and the time step is taken as \( 10^{-3} \). Shown in Fig. 19 is the interface shape at times \( t = 0.125, 0.25, 0.35, 0.4, 0.5 \) and 0.575. The bottom bubble follows and catches the top one, and the results are in good agreement with those reported by Sousa et al [24] and Marchandise et al [25].
4. Conclusions

A new finite element space $Q_h^\Gamma$ has been proposed, which has the same unknowns as the $P_1$-conforming space but consists of functions that are discontinuous across a given interface $\Gamma$, assumed not aligned with the mesh. The proposed space is much simpler than the one proposed by Gross and Reusken [2], which is based on XFEM enrichment, and also to the one proposed by Fries and Belytschko [26], which avoids introducing additional unknowns by switching to a moving-least-squares approximation in the vicinity of $\Gamma$.

Through numerical tests it was shown that the $L^2(\Omega)$-interpolation accuracy of $Q_h^\Gamma$ for functions that are smooth outside $\Gamma$ is $O(h^{3/2})$. This is a significant improvement with respect to the accuracy of continuous spaces of any polynomial degree, which is $O(h^{1/2})$.

An interpolation accuracy of $O(h^{3/2})$ in the $L^2(\Omega)$-norm is suboptimal for piecewise linear elements. However, the a priori estimate (11) implies that the space $Q_h^\Gamma$, when taken as pressure space, will not limit the accuracy of a (Navier-)Stokes calculation neither in equal-order velocity-pressure approximations, nor in the mini-element approximation. In fact, in both cases the global accuracy is limited by the $H^1(\Omega)$-accuracy of the velocity space, which is $O(h)$.

The proposed space is easy to implement, requiring just local operations at the element level to incorporate the improved pressure interpolation. Several tests were reported which illustrate the improved behavior of both velocity and pressure when the elements cut by the interface are treated with the proposed pressure interpolants.

Some issues are left for future work. A rigorous proof of the interpolation
estimate has been undertaken by Agouzal and Buscaglia, of which some preliminary results have already been communicated [27] and a complete version is in preparation. Another open theoretical question concerns the stability estimates for the $V_h$-$Q_h^\Gamma$ pair, of which strong numerical evidence has been provided in this article but whose proof is far from evident. Finally, it would be interesting to devise spaces analog to $Q_h^\Gamma$ when the overall discretization is $P_k$-conforming with $k > 1$, but this is, again, far from being an immediate extension of the space proposed in this article.
